This letter reports effective passivation of crystalline silicon (c-Si) surfaces by thermal atomic layer deposited zirconium oxide (ZrOx). The optimum layer thickness and activation annealing conditions are determined to be 20 nm and 300 °C for 20 min. Cross-sectional transmission electron microscopy imaging shows an approximately 1.6 nm thick SiOx interfacial layer underneath an 18 nm ZrOx layer, consistent with ellipsometry measurements (~20 nm). Capacitance–voltage measurements show that the annealed ZrOx film features a low interface defect density of $1.0 \times 10^{11}$ cm$^{-2}$eV$^{-1}$ and a low negative film charge density of $-6 \times 10^{10}$ cm$^{-2}$. Effective lifetimes of 673 μs and 1.1 ms are achieved on p-type and n-type 1 Ω cm undiffused c-Si wafers, respectively, corresponding to an implied open circuit voltage above 720 mV in both cases. The results demonstrate that surface passivation quality provided by ALD ZrOx is consistent with the requirements of high efficiency silicon solar cells.

Crystalline silicon (c-Si) solar cells remain the most successful photovoltaic technology due to a combination of high power conversion efficiency and low manufacturing cost. One of the key enablers in achieving high performance has been the passivation of the dangling bonds usually present on the silicon wafer surfaces. The most extensively explored, and implemented in industry, materials to suppress defect-assisted Shockley-Read-Hall (SRH) recombination are thermally grown or plasma deposited thin films of silicon oxide (SiOx),3 silicon nitride (SiNx),2,3 amorphous silicon (a-Si),1 and aluminium oxide (Al2O3).5,6 Recently, a range of transition or post-transition metal oxides have also been demonstrated to provide high quality passivation of silicon surfaces, including titanium oxide,7,8 hafnium oxide,9-12 gallium oxide,13 and tantalum oxide.14,15

Zirconium oxide (ZrOx) is another transition metal oxide having high potential to be compatible with photovoltaic applications, as it has reasonable optical properties (i.e., a relatively high refractive index and a negligible absorption in the visible range) to be used as antireflection coating.16 It has also been reported to provide some passivation of titanium oxide surfaces.17 In the semiconductor industry, ZrOx has been extensively investigated as an alternative to SiOx as a gate insulator due to its high dielectric constant (~25), insulating properties, and relatively good thermal stability.18-20 Indeed, binary alloy systems of ZrOx/alumina or ZrOx/ytria have been patented for the antireflection and passivation of silicon surfaces.21,22 However, no scientific details have yet been published on such an ability of ZrOx to suppress surface recombination in c-Si photovoltaic devices.

In this letter, we present evidence of effective surface passivation of c-Si by ZrOx prepared by atomic layer deposition (ALD). The structure, composition, and interfacial characteristics of this passivating layer are examined using cross-sectional transmission electron microscopy (TEM) and x-ray photoelectron spectroscopy (XPS). The passivation quality is then evaluated on undiffused p-type and n-type c-Si wafers. Furthermore, capacitance–voltage (C–V) measurements and X-ray diffraction (XRD) are undertaken to probe the electronic and crystal properties of ZrOx films before and after thermal annealing to elucidate the physical mechanisms underlying the evolution in surface passivation.

The ZrOx films were deposited in a thermal ALD system (Cambridge Savannah) using TEMAZ [Tetra(ethylmethylamido) zirconium] as the zirconium precursor, H2O as the oxidant, and N2 as the purge gas. The deposition was performed at 150 °C and had a corresponding rate of 1.33 Å/cycle as measured by ex-situ spectroscopic ellipsometry (J.A. Woollam M2000 ellipsimeter) and also was confirmed by the high resolution TEM presented in Fig. 1(a). The cross section of the ZrOx film was prepared using a focused ion beam (FIB) lift-out technique in a Helios NanoLab 600 DualBeam SEM/FIB system. Note that the film used for TEM is after thermal annealing (300 °C for 20 min in air), which is required to activate the passivation capability by ZrOx. TEM images were taken using a JEOL ARM200F microscope operating at 200 kV. As shown in Fig. 1(a), there exists an approximately 1.6 nm thick interfacial layer and a ~18 nm thick ZrOx layer. The interfacial layer is typically observed for ALD deposited films5,6 and likely resultant from exposure to water during the first few ALD cycles and/or possible reactions between ZrOx and the c-Si surface. Furthermore, the TEM also reveals that the ZrOx film after annealing exhibits partial crystallization, which is validated by the XRD measurements presented in Fig. 1(b).

XRD measurements were performed on ZrOx coated single-side polished c-Si wafers, using a PANalytical X’Pert PRO MRD diffractometer with an X-ray parabolic mirror and a parallel plate collimator (0.27°). The diffraction patterns were obtained by Ni-filtered Cu Ka radiation and
analysed using the software package MDI Jade. Figure 1(b) plots the XRD pattern of ZrO\textsubscript{x} films as deposited at 150°C and annealed at 300°C. As can be seen, the as-deposited film exhibits very weak diffraction features apart from a peak at 35°, indicating that the film may have some localised crystal nucleation, but is predominantly amorphous. In contrast, the film after thermal annealing shows strong and distinctive diffraction features, consistent with the partial crystallization revealed by TEM in Fig. 1(a).

XPS measurements were performed to determine the stoichiometry of ALD ZrO\textsubscript{x} films before and after annealing. Figure 2 shows the core levels of Zr 3d and O 1s. While the Zr 3d spectra show typical doublet peaks located at 182 eV and 184.5 eV for Zr 3d\textsubscript{5/2} and Zr 3d\textsubscript{3/2}, respectively, the O 1s spectra can be fitted with two Gaussian components with peaks positioned at 530 eV and 531.5 eV, respectively. 23,24 The small peak located at 531.5 eV is usually attributed to hydroxyl groups although sometimes it can also be due to surface contamination. The component with lower binding energy peaked at 530 eV can be attributed to Zr–O binding. Notably, the peak positions for both Zr 3d and O 1s are observed to be the similar for the zirconia films before and after thermal annealing. The extracted zirconia film stoichiometry (i.e., O to Zr atomic fraction) based on core level peak areas is determined to be 2.0 and 1.8 for the film before and after annealing, respectively, implying that the thermal annealing process makes the film slightly sub-stoichiometric.

To evaluate surface passivation of c-Si by the deposited dielectric, 1 Ω cm n-type and p-type c-Si substrates with a thickness of 200 μm were symmetrically coated with ALD ZrO\textsubscript{x} films. All wafers were float-zone (FZ) grown and {100} oriented. The undiffused wafers were etched in tetramethylammonium hydroxide (TMAH, 25 wt. %) at ~85°C to remove saw damage. All samples were then cleaned by the RCA (Radio Corporation of America) procedure and dipped in 1% diluted HF acid to remove any remaining oxide prior to deposition. The effective carrier lifetime $\tau_{eff}$ as a function of excess carrier density $D_n$ was measured using a Sinton Instruments WCT-120 photoconductance tool. 25 Neglecting Shockley–Read–Hall recombination in the bulk of the wafer, the upper limit of the effective surface recombination velocity $S_{eff,UL}$ was calculated according to $S_{eff,UL} = \frac{W}{2} \left( \frac{1}{\tau_{eff}} - \frac{1}{\tau_{intrinsic}} \right)$, where $W$ is the c-Si substrate thickness and $\tau_{intrinsic}$ is the intrinsic bulk lifetime of c-Si as parameterized by Richter et al. 26

Figure 3 shows the measured effective lifetime provided by as-deposited and thermally activated ZrO\textsubscript{x} films on p-type and n-type 1.0 Ω cm undiffused c-Si wafers. As can be seen, the as-deposited ZrO\textsubscript{x} provides some surface passivation on both p-type and n-type wafers with a $\tau_{eff}$ value around 40 μs at $\Delta n = 10^{15}$ cm\textsuperscript{-3}. Upon thermal annealing at 300°C for 20 min on a hotplate in air, the level of surface passivation is vastly improved by more than one order of magnitude, resulting in...
$\tau_{\text{eff}}$ as high as 673 $\mu$s and 1.1 ms at $\Delta n = 10^{15}$ cm$^{-3}$ on $p$-type and $n$-type c-Si, respectively. These lifetimes correspond to $S_{\text{eff,UL}}$ values of 13 cm/s and 8 cm/s and to implied open circuit voltages of 721 mV and 726 mV, respectively. The obtained $S_{\text{eff,UL}}$ by ZrO$_x$ is slightly higher than that by conventional passivation layers such as SiNx or Al$_2$O$_3$ and comparable to that by HfO$_2$, as summarized in Ref. 12.

C–V measurements were performed to evaluate the physical mechanisms for the substantial improvement in surface passivation upon thermal annealing, using a contactless corona charging method (Semilab PV2000A) on the same $n$-type and $p$-type c-Si samples used for the effective lifetime measurements. 27 The extracted interface defect density $D_{\text{it}}$ and effective film charge density $Q_{\text{eff}}$ are summarised in Table I. The results show that the as-deposited film presents a significant amount of defects at the ZrO$_x$/c-Si interface of $1.51 \times 10^{12}$ cm$^{-2}$ eV$^{-1}$, which is then drastically reduced by more than one order of magnitude to a level of $1.0 \times 10^{11}$ cm$^{-2}$ eV$^{-1}$ after annealing. The reduction in $D_{\text{it}}$ is commonly ascribed to the hydrogenation of dangling bonds at the dielectric/c-Si interface, for example, for the case of passivation by SiNx, a-Si, and Al$_2$O$_3$. This could also be the case for ZrO$_x$ passivation since the precursor is a hydrogen-containing organometallic compound. The effective charge density is at the order of $10^{10}$ cm$^{-2}$ for both as-deposited and annealed samples, which is low compared to the charge density typically found in conventional silicon nitride or alumina films (i.e., $\sim 10^{12}$ cm$^{-2}$). 28,29 The thermal annealing switched the charge from positive $4.4 \times 10^{10}$ cm$^{-2}$ to negative $5.8 \times 10^{10}$ cm$^{-2}$. The cause of the charge polarity change is still under investigation. Consistent results were obtained on both $n$-type and $p$-type substrates. Nevertheless, the substantial improvement in surface passivation by ZrO$_x$ upon thermal annealing appears to be primarily attributable to a reduction in the interface defect density rather than to an increase in charge density since $Q_{\text{eff}}$ is reasonably low.

The passivation quality by ZrO$_x$ is shown in Fig. 4 to exhibit a strong dependence on film thickness, thermal annealing temperature, and time. As the film thickness increases, the effective lifetime first increases sharply and peaks at 20 nm. The passivation seems slightly less effective when ZrO$_x$ becomes thicker. This thickness dependence is similar to that exhibited by ALD hafnium oxide presented by Cui et al., 12 presumably due to higher crystallinity of thick films upon thermal annealing. A similar behaviour was observed for the dependence of thermal annealing temperature and time, showing an optimum condition at 300°C for 20 min. It is worth mentioning that the degradation of passivation upon annealing above 300°C could also be due to deterioration of silicon bulk quality, as presented in Ref. 30. As presented before, the thermal annealing activates the passivation by the ZrO$_x$ film primarily through the reduction in interface defect density. The process window of annealing duration seems reasonably wide between 10 and 30 min. Note that the annealing was conducted on a hotplate in air.

TABLE I. Interface defect density $D_{\text{it}}$ and effective fixed charge density $Q_{\text{eff}}$ for ZrO$_x$ films.
Our preliminary study of annealing in forming gas in the thermal furnace shows similar trends but slightly poorer passivation quality. The reason for this behaviour is still unknown to us and warrants further investigation.

In conclusion, we have shown effective surface passivation of c-Si wafers by thermal ALD ZrO$_x$ with an optimum thickness at 20 nm and annealing at 300 °C for 20 min in air ambient. Effective lifetimes of 673 μs and 1.1 ms were achieved on p-type and n-type 1Ω cm undiffused wafers, respectively, corresponding to $S_{eff,UL}$ values of 13 cm/s and 8 cm/s and an implied $V_{OC}$ above 720 mV. C–V measurements revealed that the annealed ZrO$_x$ film features a low $D_h$ of $1.0 \times 10^{11}$ cm$^{-2}$ eV$^{-1}$ and a low negative $Q_{eff}$ of $-6 \times 10^{-10}$ cm$^{-2}$. The demonstrated high passivation by ALD ZrO$_x$ paves the way for its application in the design and fabrication of high efficiency silicon solar cells.

We would like to thank Dr. Jason Cui for XRD measurements and analysis and Dr. Ziv Hameiri and Mr. Kyung Kim for contactless corona CV measurements and analysis.
