Beeman,\textsuperscript{a,b,c} James Bullock,\textsuperscript{d} Hao Wang,\textsuperscript{a,d} Johanna Eichhorn,\textsuperscript{a} Clarissa Towle,\textsuperscript{a,b,c} Ali Javey,\textsuperscript{d} cd Francesca M. Toma,\textsuperscript{a} Nripan Mathews\textsuperscript{a,e} and Joel W. Ager\textsuperscript{a,b,c}

Si photocathodes integrated with Ag-supported dendritic Cu catalysts are used to perform light-driven reduction of CO\textsubscript{2} to C\textsubscript{2} and C\textsubscript{3} products in aqueous solution. A back illumination geometry with an n-type Si absorber was used to permit the use of absorbing metallic catalysts. Selective carrier collection was accomplished by a p\textsuperscript{+} implantation on the illumination side and an n\textsuperscript{+} implantation followed by atomic layer deposition of TiO\textsubscript{2} on the electrolyte site. The Ag-supported dendritic Cu CO\textsubscript{2} reduction catalyst was formed by evaporation of Ag followed by high-rate electrodeposition of Cu to form a high surface area structure. Under simulated 1 sun illumination in 0.1 M CsHCO\textsubscript{3} saturated with CO\textsubscript{2}, the photovoltage generated by the Si (\textapprox 600 mV) enables C\textsubscript{2} and C\textsubscript{3} products to be produced at \textapprox 0.4 vs. RHE. Texturing of both sides of the Si increases the light-limited current density, due to reduced reflection on the illumination side, and also decreases the onset potential. Under simulated diurnal illumination conditions photocathodes maintain over 60\% faradaic efficiency to hydrocarbon and oxygenate products (mainly ethylene, ethanol, propanol) for several days. After 10 days of testing, contamination from the counter electrode is observed, which causes an increase in hydrogen production. This effect is mitigated by a regeneration procedure which restores the original catalyst selectivity. A tandem, self-powered CO\textsubscript{2} reduction device was formed by coupling a Si photocathode with two series-connected semitransparent CH\textsubscript{3}NH\textsubscript{3}PbI\textsubscript{3} perovskite solar cells, achieving an efficiency for the conversion of sunlight to hydrocarbons and oxygenates of 1.5\% (3.5\% for all products).

Broader context
Sunlight-driven conversion of carbon dioxide and water into useful chemical and fuels is of fundamental and technological interest. Widespread adoption of such a technology could slow the rate of carbon dioxide emissions into the atmosphere by replacing chemicals obtained from oil with sustainably generated alternatives. Here, a silicon-based photocathode is coupled to inexpensive halide perovskite solar cells, producing C\textsubscript{2}, products with an efficiency greater than that of photosynthesis.

Introduction
An environmentally sustainable future will require significant changes in all aspects of energy conversion.\textsuperscript{1,2} Developing an alternative to unsustainable fossil fuel extraction and combustion is a critical priority to slow down and eventually stabilize the rise of CO\textsubscript{2} levels in the atmosphere and in the oceans.\textsuperscript{3} A number of technical approaches have been proposed to use renewable energy sources to convert CO\textsubscript{2} to useful chemicals and/or fuels, including thermochemical, high temperature electrochemical, thermolysis electrochemical and photovoltaic chemical (PEC) methods.\textsuperscript{4} Of these, systems which replicate the functions of photosynthesis,\textsuperscript{5,6} which synthetically converts CO\textsubscript{2} to more reduced forms (photosystem I and Calvin cycle) and oxidize water to oxygen (photosystem II), are both intellectually and technologically interesting.\textsuperscript{7-9}
There is an analogy between the Z-scheme configuration of photosystems I and II and a tandem solar cell, as both generate chemical potential differences in their sub-components that add together to produce electricity or drive a chemical reaction. In the case of photosynthesis, the generated chemical potential difference enables the requisite carbon dioxide reduction and oxygen evolution reactions (CO$_2$R and OER, respectively) to occur. Indeed, this concept has been utilized in solar-driven electrochemical water splitting devices which produce hydrogen as the reduction product.$^{11,12}$ A commonly-used motif in these types of devices is the use of high and low band gap absorbers to maximize the attainable voltage.$^{13}$ Either or both of the absorbers can be in contact with the electrolyte, forming a photocathode in the case of the reduction reaction and a photoanode in the case of oxidation.$^{11,14,15}$

Solar-driven electrochemical CO$_2$R has the potential to efficiently and selectively drive the production of energy dense hydrocarbons and provide an alternative to fossil fuels that can exploit existing infrastructures, thus becoming more appealing than the similar approach used for hydrogen production. Also, it is notable that for systems driven by CO$_2$ dissolved in an aqueous electrolyte, the mass transfer limited current density, which on the order of a few 10’s of mA cm$^{-2}$, are a good match to the current densities provided by solar cells under 1 sun illumination.$^{17}$ For this reason, photocathodes which drive CO$_2$R reactions directly would be expected to perform well in this light limited photocurrent regime.

Although far fewer in number compared to water splitting, there have been a number of recent demonstrations of solar-powered CO$_2$R, some of which have reported overall energy conversion efficiencies above 1%.$^{18-26}$ Notably, most of these demonstrations employ photocatalytic elements which are isolated from the electrochemistry; exceptions are studies which use an illuminated photoanode to drive the water oxidation reaction (OER) with a dark cathode employed for CO$_2$R.$^{20,21}$ Urbain et al. reported a CO$_2$ reduction prototype reactor containing a Si photoanode coupled to Ni foam as an OER catalyst and a Cu foam with Zn flakes as the cathode with a solar to syngas conversion efficiency of 4.3%.$^{22}$ Significantly, Asadi et al. combined a 3 junction amorphous Si solar cell with a WSe$_2$ CO$_2$R catalyst to make an artificial leaf, achieving an overall 4.6% conversion efficiency to all products and a 20% FE for CO.$^{27}$ In the solar thermal study of Marxer et al., a 4 kW solar reactor was coupled to a porous ceria catalyst to achieve a solar to CO conversion efficiency of 5.25%.$^{28}$

Thus, a photocathode which can drive the CO$_2$ reduction reaction is desirable for increasing the design space of CO$_2$R devices in general and also enabling the fabrication of integrated devices.$^{11}$ However, there are relatively few reports of photoelectrochemical reduction of CO$_2$ using semiconducting photoelectrodes.$^{28-31}$ Halmann reported in 1978 the formation of formic acid, formaldehyde, and methanol by p-GaP photoanodes,$^{32}$ although later work by Sears and Morrison associated some of the observed products with corrosion processes.$^{13}$ There are intriguing reports of methanol formation from III–V photocathodes,$^{34-36}$ but the mechanism by which this product forms has not been clarified.$^{37-40}$ Also notable are studies which interface molecular catalysts to p-Si to produce 2-electron reduction products such as CO.$^{41,42}$ An example of this type of study is the work of Song and co-workers in which a Si photocathode with a nanoporous Au thin film produced CO with 96% faradaic efficiency (FE).$^{43}$ Graphene has also been used as a co-catalyst for selective conversion of CO$_2$ to CO using p-Si nanowire photocathodes.$^{44}$

Natural photosynthesis produces C$_3$ and C$_4$ sugars.$^{45}$ The question thus arises whether a light-driven artificial system can make C–C coupled products with equivalent or, ideally, greater efficiency. From the point of view of economic value and commercial market size, C$_2$, hydrocarbons and oxygenates are desirable due to their high energy densities and compatibility with the established petroleum processing infrastructure.$^{46}$ In electrocatalytic investigations of CO$_2$ reduction, heterogeneous catalysts, specifically Cu and bimetallic alloys containing Cu, are employed to produce C–C coupled products as they can generate C$_2$ and even C$_3$ products.$^{47-51}$ While there are exceptions, when heterogeneous CO$_2$ reduction catalysts are coupled to photocathodes, a product distribution similar to that of the electrocatalyst operated by itself is produced, albeit with a cathodically shifted onset potential due to the photovoltage.$^{52}$ However, there are only a few reports of the formation of C–C coupled products using CO$_2$R photocathodes. As one example, Nakato and co-workers employed p-Si interfaced with Cu nanoparticles to produce a C$_2$ (ethylene) and C$_1$ (CO, methane) products although a full faradaic efficiency analysis was not performed.$^{53}$

The challenge of performing photocathodic conversion of CO$_2$ to C$_2$ and C$_3$ products (e.g. ethylene, ethanol, propanol) forms the motivation for this study. The architecture we employed is shown schematically in Fig. 1. In contrast to prior Si photocathode studies we chose n-type silicon as the absorber, using charge selective contacts to control the device polarity.$^{54-56}$ Selective hole collection was achieved by a p$^+$ implanted layer on the illumination face, along with texturing to reduce the reflectivity and maximize the number of absorbed photons.

The choice of materials on the side of the photocathode which will contact the electrolyte requires significant care. An n$^+$ implanted layer was used to create a selective electron contact, and a textured surface was employed to increase the surface area available for catalysis. A thin (10 nm) layer of TiO$_2$ was used to perform 3 functions: (1) passivate the surface, (2) transport electrons to the catalyst, and (3) prevent in-diffusion of Cu from the catalyst into the Si. Finally, we employed an electrochemically deposited high surface area Ag-supported dendritic Cu catalyst which we have previously shown to produce C$_2$ products (hydrocarbons and oxygenates) over a wide range of voltage and current density operating conditions.$^{23}$ A number of studies have shown that high surface area, dendritic catalysts, can support relatively high current densities for CO$_2$R.$^{57-60}$ For example, Urbain et al. reported that Ag dendrites formed on Cu foam have high activity (>27 mA cm$^{-2}$) and selectivity (85–96%) for CO formation.$^{57}$ Here, we will show that an integrated photocathode can achieve overall CO$_2$R with faradaic efficiencies (FEs) of over 80%,
with faradaic efficiencies (FEs) to \( \text{C}_2\text{C}_3 \) products as high as 70%. Notably, we developed a method to regenerate the catalytic surface and demonstrated continuous operation over 20 diurnal illumination cycles. The back illuminated geometry is well suited for integration with a higher band gap absorber situated optically and electrically in series. Using this design, we demonstrated integrated, unbiased \( \text{CO}_2 \) reduction using two semi-transparent halide perovskite solar cells coupled to the photocathode, achieving a 1 sun overall solar to chemical energy conversion efficiency of 3.5% (1.5% to hydrocarbons and oxygenates).

**Results and discussion**

**Si photocathode for \( \text{CO}_2 \) reduction**

Fig. 2 shows the electrocatalytic interface comprised of the textured Si and Ag-supported dendritic Cu \( \text{CO}_2 \text{R} \) catalyst (see ESI† for fabrication details). It can be seen that the electrochemical deposition method we employed favours nucleation at the tips of the texture pyramids, Fig. 2a, creating a “nano-cactus” morphology formed by Cu dendrites \( \sim 100 \text{ nm} \) in length (also see Fig. S7a–c, ESI†). Fig. 2b shows that the catalyst completely covers the textured Si. We found that complete coverage of the pyramids was essential to sustain the \( \text{CO}_2 \) reduction process. In cases of less complete coverage, hydrogen production became dominant over time, which would be expected if exposed TiO\(_2\) were reduced to Ti metal, which is known to be a catalyst for the hydrogen evolution reaction (HER).\(^47\) Au-supported dendritic Cu catalysts were also fabricated by a similar process; they also have a high-branched morphology, Fig. S7d, e and S8 in ESI†. XRD and XPS analyses were used to show that Cu partially covers the support metal and that both metals are exposed at the surface (Fig. S9 and S10, ESI†).

Photoelectrochemical (PEC) measurements were carried out in 0.1 M CsHCO\(_3\) electrolyte (pH = 6.8), under simulated sunlight illumination at AM 1.5G 100 mW cm\(^{-2}\) from a 150 W xenon lamp (see ESI† for details). We and others have previously shown that use of the Cs\(^+\) cation, as opposed to the more typically used K\(^+\), encourages formation of \( \text{C}_2\text{C}_4 \) products on Cu-based catalysts.\(^{59,61,62}\) A three-electrode electrochemical configuration was used (Fig. 3a and Fig. S2, ESI†), using a Si photocathode as the working electrode, an Ag/AgCl reference electrode, and an IrO\(_2\) counter electrode; both electrodes had an active area of 1 cm\(^2\). An anion conduction membrane was used to separate the cathode and anode chambers of the cell.

Fig. 3b compares the linear sweep voltammograms for textured and planar photocathodes with the Ag-supported dendritic Cu catalyst. Data from a dark planar cathode (n\(^+\) wafer with the same catalyst but without the hole-selective p\(^+\) back contact, see ESI,† Fig. S1 for implantation profiles) are also shown. Neither photocathode generates cathodic current in the dark, as expected from the presence of the hole-selective back contact which blocks electrons in the absence of light. The dark control displays a current onset at about \(-0.75 \text{ V} \) vs. RHE, which is similar to what we have observed previously for these types of Ag-supported dendritic Cu catalysts by themselves.\(^{23}\) For both photocathodes, there is a cathodic shift of the onset potential due to the photovoltage from the Si, and the expected light-limited current density is observed at larger cathodic potentials. The textured photocathode has both a less cathodic onset potential and a higher current density at all potentials.
compared to the planar control, which we attribute to superior light capture on the illumination side and to effective selective charge collection and suppression of surface recombination at both interfaces. From the shift of the $J$–$V$ curve of the planar photocathode compared to the dark control, a photovoltage of 550–650 mV is inferred (see ESI,† for calculation details and Fig. S14). These values are comparable to those achieved with implanted contacts in other PEC applications.63,64 Similar $JV$ data for photocathodes with AuCu catalysts are shown in Fig. S12, ESI.†

Fig. 3c and d show the product distribution for the illuminated planar and textured photocathodes with the Ag-supported dendritic Cu catalyst at voltages between $-0.4$ and $-1.0$ V vs. RHE. At a given voltage the product distribution for photocathodes is similar and both show a trend of decreasing $\mathbf{H}_2$ production (i.e. increasing selectivity to CO$_2$ reduction) as the potential increases. Similar CO$_2$R product distributions were observed when testing the Si photocathode with an Au-supported dendritic Cu catalyst (Fig. S13, ESI†). Interestingly, even though the geometric current density for the textured photocathode is very high ($\sim$30 mA cm$^{-2}$) at the maximum power point, $-1.0$ V vs. RHE, we did not observe evidence of CO$_2$ depletion due to mass transfer limitations at the catalyst surface, which would have resulted in an increased rate of $\mathbf{H}_2$ production. We attribute the ability to operate at high current densities, on the order of the light limited current density for a Si absorber, to the high surface area of the integrated catalyst (electrochemically active surface area of the Ag-supported dendritic catalysts is about an order of magnitude larger than evaporated Cu deposited on planar Si, see Fig. S11 and ESI† for details). Electrochemical impedance spectroscopy (EIS) analyses were also carried out to evaluate the charge transfer behaviour from planar and textured photocathodes (see ESI† and Fig. S3, S4).

At all potentials in Fig. 3c and d, CO$_2$R is the dominant reaction, with the FE for the competing hydrogen evolution reaction (HER) decreasing with increasing cathodic bias; at $-1.0$ V vs. RHE the FE for HER is very low: only 16% and 18% for the planar and textured photocathodes, respectively. Within the CO$_2$R
products, ethylene is dominant at all potentials, and ethanol has the highest FE among the oxygenates, followed by 1-propanol. The planar and textured Si photocathodes show similar selectivity (79% \pm 6% and 78% \pm 5%) for hydrocarbons and oxygenates at \(-1.0\) \text{V vs. RHE}. These values are substantially higher than those achieved by previously reported Si photocathodes at under similar conditions,\(^6^5\) which we attribute to the large loading of the catalyst and the back illumination geometry.

To determine whether there are any major differences in the product distribution under dark and light driven conditions, we selected potentials, which produce similar current densities, and thus similar local \(\text{CO}_2\) concentration and pH, for the two cases. For a current of \(10\) \text{mA cm}^{-2},\(^6\) examination of Fig. 3b shows that a bias of \(-1.1\) \text{V vs. RHE} is required for the dark cathode and \(-0.55\) \text{V vs. RHE} for the planar Si photocathode respectively. Evaluation of the product distribution under these conditions did not reveal any significant differences, as we expected for our design (Fig. S15, ESI\(^\dagger\)). To evaluate the specific role of Ag support, we fabricated Cu-supported dendritic Cu catalysts of similar morphology on planar n+-Si; these had comparatively lower selectivity to C–C coupled products and to \(\text{CO}_2\text{R}\) in general (see ESI\(^\dagger\) and Fig. S28 and S29 for details).

**Evaluation and management of stability**

Solar to chemical energy conversion schemes must operate stably for years to be environmentally and economically viable.\(^6^6–^6^8\) This is particularly important for integrated devices, as failure of any one of the components would require remanufacturing of the entire device. We simulated diurnal cycling by operating textured photocathodes at \(-0.4\) \text{V vs. RHE} and under 1 sun conditions for 10 hours followed by 14 hours off. After each day of testing, the electrolyte was replaced and an analysis of the liquid products was performed (gas products were measured every 15 minutes during illuminated operation). The pH of the electrolyte was measured to evaluate the dissolved \(\text{CO}_2\) concentration, which remained close to the expected saturation value (see ESI\(^\dagger\) for details and Fig. S27). Fig. 4a and b show the results of 10 days of testing of a Si photocathode. The current density was relatively constant in the range of \(8–10\) \text{mA cm}^{-2}, with a small increase in the first 8 days, followed by a decrease (Fig. S16, ESI\(^\dagger\)). However, after 2 days, the FE for \(\text{H}_2\) production, initially only 20%, began to increase, which is likely due to catalyst regeneration.

![Fig. 4](https://www.energyenvironmentalscience.org/content/4/4/1068/full)
reaching nearly 60% after 10 days. The FE for the major CO$_2$R products—ethylene, ethanol, and propanol—decreased, particularly near the end of the test period, while the FE for CO was found to rise. We note that under these test conditions, the measured total FE for all products can be less than 100%, which is attributed to the evaporation of some liquid products over the 10 hour test period due to the continuous purging of the cell with CO$_2$.

The origin of the decrease in the CO$_2$R selectivity during sustained operation was investigated. Examination of the catalyst after 10 days of operation by SEM revealed no apparent changes in its morphology (Fig. S17, ESI†). However, XPS analysis of the photocathode surface revealed the presence of Ir (Fig. S18c, ESI†), to which we attribute the increasing H$_2$ selectivity. This type of cathode contamination by metals from the counter electrode has been observed previously in CO$_2$ electrolysis cells and appears to be only partially mitigated by the use of an anion conducting membrane. $^{24}$

Replacing the IrO$_2$ counter electrode with Pt exacerbated the contamination effect with H$_2$ production becoming dominant after only 2 days (Fig. S19c, ESI† shows XPS observation of Pt on the photocathode). Use of CoPi as a counter electrode increased the required cell voltage by 1 V, but appeared to mitigate somewhat cathode contamination (Fig. S25 and S26, ESI†). This material could be an alternative, less costly, anode if the overpotential could be reduced to values comparable to IrO$_2$.

To mitigate contamination from the counter electrode, we developed a catalyst regeneration scheme, which consists of careful mechanical removal of some of the copper from the photocathode surface and redeposition of fresh dendritic Cu using our electrochemical process (see ESI† for photocathode regeneration process and Fig. S20). A similar regeneration strategy was used previously to extend the lifetime of a Si photoanode used for water oxidation. $^{64}$ Fig. 4c and d summarize the results of an additional 10 days of testing of a regenerated photocathode. Comparing the FEs for day 10 and day 11 (Fig. 4b and d), it is clear that the regeneration process restores the selectivity for CO$_2$ reduction, with the selectivity of the competing hydrogen evolution reaction being reduced from 60% to 30%.

Compared to day 1, the current density immediately after regeneration (day 11) was slightly lower, and the FEs for H$_2$ (30% vs. 22%) and CO (12% vs. 8%) were higher. Examination of the morphology of the regenerated catalyst finds the Cu redeposition tends to nucleation and grow on existing dendrites as opposed to on the underlying Ag (Fig. S21, ESI†), leading to more Ag sites exposed to the electrolyte, which is consistent with the increased FE to CO. Notably, the regenerated photocathode maintains selectivity to CO$_2$R longer than the originally fabricated one. Both the current density and the FE for H$_2$ increase with time, both of which could be attributed to cross-contamination from the counter electrode, but the rate of increase of the FE for H$_2$ production is slower, reaching only 40% on day 20. The slower loss of selectivity can be attributed to the higher loading of Cu on the regenerated catalyst, so that contaminants occupy a smaller fraction of the overall surface area.

**Self-powered CO$_2$ reduction device**

A self-powered CO$_2$R device must provide the thermodynamic potential for the desired reduction reaction at the cathode and for water oxidation at the anode, plus overpotentials and voltage losses in the cell. The thermodynamic potential for CO$_2$R is 1.1–1.3 V depending on the product, the overpotential for C$_2$ product formation is ca. 1.0 V, the overpotential for water oxidation is ca. 0.4 V at the current densities we employ, and the cell losses are estimated at 0.2 V. Adding these values leads to target voltage of 2.7 V. As the Si photocathode can provide up to 0.6 V, additional driving elements must provide at least 2.1 V. This analysis leads to our choice of two semi-transparent halide perovskite solar cells, as this class of cells has both a tunable band gap in the range of 1.6–2.0 eV and a relatively high open circuit voltage compared to other materials with similar band gaps (Fig. S23, ESI†). To couple the perovskite solar cells optically in series with the Si photocathode, they must be semi-transparent, transmitting light below their band gaps to the Si. Historically, it has been difficult to make semi-transparent halide perovskite solar cells with similar performance to opaque cells due to cell damage occurring during the fabrication of the transparent contact. Here, we used a very low energy sputtering process to form this contact, which resulted in cells of acceptable performance for this application (see ESI† for cell fabrication details).

To form a self-powered CO$_2$ reduction device, two semi-transparent halide perovskite [Cs$_{0.05}$(MA$_{0.17}$FA$_{0.83}$)$_{0.55}$Pb(I$_{0.85}$Br$_{0.17}$)$_{3}$] solar cells were connected electrically in series with the PEC cell, using a geometry similar to one employed previously for water splitting. $^{69,70}$ The cells have a band gap of 1.58 eV and 1 sun performance parameters as follows: short circuit current ($I_{SC}$) = 14.5 mA cm$^{-2}$, open circuit voltage ($V_{OC}$) = 1.06 V, fill factor (FF) = 0.55, and an overall power conversion efficiency (PCE) = 8.4%. Fig. 5a depicts the device geometry with two semi-transparent cells masked to expose 0.5 cm$^2$ used as top absorbers and a Si photocathode with an active area of 1 cm$^2$ was used as the bottom absorber (see also photo, Fig. S22, ESI†).

As shown in Fig. 5b, the two series-connected semitransparent solar cells (0.5 cm$^2$ each) provide a $V_{oc}$ of 2.1 V and a short circuit current ($I_{sc}$) of 5.8 mA under 1 sun (AM 1.5G, 100 mW cm$^{-2}$) illumination, with the voltage meeting the minimum criterion discussed above. A range of electrolyte concentration (0.1–0.5 M CsHCO$_3$) was used to investigate the role of resistance losses in the electrochemical cell. Two-electrode measurements of the Si photocathode itself and shaded by the perovskite solar cells are also shown in Fig. S24 (ESI†) and Fig. 5b. At a given voltage, the current in the photoelectrochemical cell increases with increasing electrolyte concentration, as would be expected due to the increased ion conductivity. The operating current ($I_{op}$) of the tandem device (perovskite/Si photocathode) is determined by the crossing point of the absolute photocurrent of Si photocathode and series-connected perovskite solar cells, Fig. 5b. The operating
currents were 2.1 to 2.9 mA at 1.95 to 1.86 V and in 0.1 to 0.5 M CsHCO₃ electrolyte concentrations, respectively.

The solar to chemical conversion performance of the tandem system was monitored by measuring the evolution of CO₂R products without external bias under constant 1 sun illumination for 1.75 h (Fig. 5c). The FE for H₂ were relatively unaffected by the electrolyte concentration while the FE for ethylene increased and the FE for the C₁ products CO and formate decreased. The solar-to-chemical conversion (STC) efficiency was calculated by the equation:

\[
\eta_{STC} = \sum \frac{I_{op} \times E^o \times FE_i}{P_{in}} 
\]

where, \(I_{op}\) is operating current, \(E^o\) is the thermodynamic potential of the respective product, \(FE_i\) is the Faradaic efficiency of the individual product and \(P_{in}\) is input power. There are more than 12 products generated and thus the total solar to chemical conversion (\(\eta_{STC}\)) efficiency is sum of all these individual conversion efficiencies (\(\eta_{STC_i}\)). The STC conversion efficiency of the tandem device was calculated based on the operating current and the selectivity of generated products.

The solar to chemical conversion efficiency for all products increases with electrolyte concentration, going from 2.5% at 0.1 M to 3.5% at 0.5 M, Fig. 5d. The efficiency for producing hydrocarbons and oxygenates also increases, going from 0.9% to 1.5% over the same range of electrolyte concentration. It could be expected that higher electrolyte concentration might yield even higher solar conversion efficiencies. However we found in our prior study which used a similar Ag-supported dendritic Cu CO₂R catalyst that electrolyte concentrations higher than 0.5 M decrease the C₂+ product selectivity.²³

Prospects for scale-up

The geometry we employed for the proof of principle self-powered CO₂R device, with the photovoltaic components beside the Si photocathode would require redesign to be scalable. However, we observe that there are precedents from standalone water splitting demonstrations showing that lateral interconnections and integration methods of the type we would need for scaling our design are technically feasible.⁷¹,⁷² Also, Si-based water-splitting devices have been demonstrated at large scale (e.g. 64 cm² by Becker et al.⁷³) and can be tiled into...
functional modules as shown by Turan et al. The processes we used to prepare the photocathodes (texturing, ion implantation, ALD, metal evaporation) either were performed at the full wafer scale or could be done with existing commercial tools. The electrodeposition process used to deposit the Cu CO2R catalyst also could be done on full Si wafers. Thus, we do not foresee any issues in producing Si photocathodes at the size of commercial PV cells, $6^\circ \times 6^\circ$.

The cell design including the anion conducting membrane is conceptually similar to commercial fuel cells. IrO2 and Pt, which we used as anode materials, are scarce and expensive and thus not favourable for large-scale application, so alternatives need to be found. In addition to the CoPt anode we investigated here, manganese based ternary oxides and perovskites perform OER at neutral pH but require higher overpotentials than the Pt and IrO2. Thus, a less expensive anode material with similar or better OER performance compared to IrO2 would be desirable for scale-up.

Finally, regarding the perovskite solar cells, there are intense efforts ongoing world-wide to scale up this technology, which has inherent cost advantages compared to Si. In particular, there are a number of recent demonstrations of large area (10–100 cm$^2$) perovskite solar cells which could be used in tandem with Si-wafer-based CO2R photocathodes in geometries similar to what we have demonstrated here.

Conclusions

A back-illuminated n-type Si photoabsorber coupled with an Ag-supported dendritic Cu catalyst forms an effective photocathode for the photoelectrochemical CO2 reduction in aqueous solution. Directional charge transport is enforced with charge-selective contacts while texturing of the Si increases light capture on the illumination side and increases the area available for electocatalysts on the electrolyte side. Integration of an Ag supported dendritic Cu catalyst enables production of C2 and C3 products such as ethylene, ethanol, and 1-propanol. A catalyst regeneration method is demonstrated which mitigates contamination of the photocathode by metals from the anode, which occurs during multi-day operation. A strategy for coupling efficient PV to a Si photocathode is used for stand alone, "no bias," solar-driven CO2 reduction, and a maximum total solar-to-chemical conversion efficiency of 3.5% to all products and 1.5% to hydrocarbons and oxygenates is reported. The modular nature of our approach allows for further improvements in solar-to-chemical conversion efficiency, which could be achieved by better power matching between the solar cells and the Si photocathode and improvements in the selectivity of the catalysts.

Author contributions

JWA and G designed the study. G synthesized photocathode and anode materials and performed all photoelectrochemical (PEC) and PV/PEC analyses. G and JB designed the ion implantation protocol and JB performed the ion implantation. JA, G, NM, and WH selected the semi-transparent perovskites PV devices which were fabricated by WH. G performed PV and PV/PEC tandem efficiency measurements. G and CT analysed FE and PV efficiency data. JE and G performed and analysed the XPS data. AJ, JB, FMT, JE, and CMT contributed to discussions of the charge collection mechanism. The manuscript was written with contributions from all of the co-authors.
